# On the Model Based Interpretation of Filters and the Reliability of Trend-Cycle Estimates

Tommaso Proietti\*

Università di Roma “Tor Vergata”

## Abstract

The paper explores and illustrates some of the typical trade-offs which arise in designing filters for the measurement of trends and cycles in economic time series, focusing, in particular, on the fundamental trade-off between the reliability of the estimates and the magnitude of the revisions as new observations become available.

This assessment is available through a novel model based approach, according to which an important class of highpass and bandpass filters, encompassing the Hodrick-Prescott filter, are adapted to the particular time series under investigation. Via a suitable decomposition of the innovation process, it is shown that any linear time series with ARIMA representation can be broken down into orthogonal trend and cycle components, for which the class of filters is optimal.

The main results then follow from Wiener-Kolmogorov signal extraction theory, whereas exact finite sample inferences are provided by the Kalman filter and smoother for the relevant state space representation of the decomposition.

**Keywords:** Signal Extraction, Revisions, Kalman filter and Smoother, Bandpass filters.

# 1 Introduction

The separation of the trend from the cycle is a major issue in the analysis of the dynamic behaviour of macroeconomic variables, such as output, unemployment and inflation. Recent contributions, and in particular Orphanides and van Norden (2002), have focussed on the issue of the uncertainty with which signals are estimated in macroeconomics: for instance, given the relevance that measures of the output gap are assigned for the conduct of monetary policy, the econometric profession should provide a clear assessment of the reliability of such measures, including, *inter alia*, the evaluation of features that are related to the properties of the signal extraction filter, such as the final estimation error and the process of revision.

When the signals are estimated within a parametric approach, as in Harvey and Jäger (1993), this assessment is a natural by product of the modelling effort. Often, however, those measures are provided by the application of *ad hoc* filters that select certain features of the series without entertaining a model of the series dynamics; in other occurrences, which are the ones considered in this paper, the filter has a genuine model based interpretation, but the underlying model is clearly misspecified for the series under investigation. In all these occurrences it may not be immediately clear how the reliability of the corresponding signals should be evaluated.

This is the case for the Hodrick-Prescott filter (Hodrick and Prescott (1997), HP henceforth): the underlying local linear trend model, that decomposes the series into uncorrelated components represented by an integrated random walk trend plus pure white noise (see section 2 below), is usually inadequate for macroeconomic time series such as real gross domestic product. If the signal to noise ratio were estimated, rather than fixed, experience suggests that its value would result so large to render the trend indistinguishable

from the series; furthermore, the usual residual based diagnostics would definitively speak out against the maintained model.

The objective of this paper is to assess two important aspects of the uncertainty of the trend-cycle estimates arising from a class of filters, considered in Pollock (2000) and Gómez (2001), and nesting popular filters such as HP and rational square wave filters: the final estimation mean square error (MSE) and the magnitude of the revision of the estimates at the end of the sample, as new observations become available.

This assessment is allowed for by the fact that the filters admit an interpretation within a model based framework: extending the approach initiated by Gómez (2001) and Kaiser and Maravall (2001), we show that it is possible to define a trend-cycle decomposition of any ARIMA process via a suitable orthogonal decomposition of the innovations. The approach is immediately generalised to bandpass filters.

The trends and cycles emerging from the decomposition are artificial, as they do not necessarily correspond to a mechanism that has generated the data; nevertheless, the decomposition furnishes the theoretical underpinning for framing the filters within the general theory of linear estimation. This assumes that the filters have autonomous justification, eg. as bandpass filters, an interpretation that we review in the course of the discussion.

Within the model-based framework, the class of filters yields the Wiener-Kolmogorov optimal filters of the components, given the availability of a doubly infinite sample. However, although the impulse responses for the central sample points are invariant, the MSE of the smoothed estimates depends on the time series model for the series. The paper provides an upper bound for it and discusses its dependence upon the filter design parameters. Moreover, the filtered estimates and the MSE of the components depend on the properties of the series under investigation, in that they vary according to the ARIMA

process considered.

In sum, the model based framework allows correct inferences on the reliability of the estimates of trends and cycles, and the paper discusses how the estimation MSE depends on both the features of series (for instance, the order of integration), and the parameters that regulate the design of the filter, discussing also the the role of smoothness priors.

The paper is organised as follows: section 2 introduces the class of filters that we concentrate upon, presenting the local trend model for which it is optimal and discussing the role of the main parameters. The frequency domain arguments which enforce the interpretation of as bandpass filters is also reviewed. Section 3 sets up the decomposition of any ARIMA process into trends and cycles that yield the same filters as the minimum mean square estimators of the components for a doubly infinite sample. In finite samples inferences are provided by the Kalman filter and smoother for the state space representation of the decomposition, which is given in the appendix. In section 4 we derive an upper bound for the MSE of the final estimate and discuss how it depends on features of the series, namely the order of integration, and the design parameters of the filter. Section 5 discusses further aspects of the uncertainty of the signal estimates. It presents an empirical example, referring to the U.S. real gross domestic product, a well known case study in the application of the HP filter, illustrating how the estimates of the cycle depend on the time series model adapted to the series, how the uncertainty is understated by the MSE outputted by the Kalman filter and smoother for the misspecified local linear trend model at the basis of the HP filter, and finally how the uncertainty depends on the cutoff frequency, and thus on the bandpass nature of the filter. The revision issue is addressed when the true model is ARIMA(1,1,0) and illustrate the fundamental trade-off between the reliability and the extent of the revision process. Section 6 deals with the model based interpretation of bandpass filters and the design of an optimal filter. In section 7 some

conclusions are drawn.

## 2 A class of trend-cycle filters

The class of filters considered in this paper arises from the application of the Wiener-Kolmogorov (WK) optimal signal extraction theory to the signal plus noise, or local trend, model:

$$\begin{aligned}
y_t &= \mu_t + \psi_t, & t = 1, 2, \dots, T, \\
\Delta^m \mu_t &= (1 + L)^n \zeta_t, & \zeta_t \sim \text{NID}(0, \sigma_\zeta^2), \\
\psi_t &\sim \text{NID}(0, \lambda \sigma_\zeta^2), & \text{E}(\zeta_t, \psi_{t-j}) = 0, \forall j,
\end{aligned} \tag{1}$$

where  $\mu_t$  is the signal, or trend, component,  $\psi_t$  is the noise,  $\Delta$  is the difference operator,  $\Delta = 1 - L$  and  $L$  is the lag operator such that  $L^j y_t = y_{t-j}$  for integer  $j$ .

The (pseudo) autocovariance generating functions (ACGF) of the components and the series are:

$$g_\mu(L) = \frac{|1 + L|^{2n}}{|1 - L|^{2m}} \sigma_\zeta^2, \quad g_\psi(L) = \lambda \sigma_\zeta^2, \quad g_y(L) = g_\mu(L) + g_\psi(L),$$

where  $|1 + L|^2 = (1 + L)(1 + L^{-1})$  and  $|1 - L|^2 = (1 - L)(1 - L^{-1})$ . Assuming a doubly infinite sample, the minimum mean square estimators (MMSE) of the components are respectively  $\tilde{\mu}_t = \mathbf{w}_\mu(L)y_t$  and  $\tilde{\psi}_t = y_t - \tilde{\mu}_t = \mathbf{w}_\psi(L)y_t$ , where  $\mathbf{w}_\mu(L) = g_\mu(L)/g_y(L)$  and  $\mathbf{w}_\psi(L) = g_\psi(L)/g_y(L)$ ; see Whittle (1983). Hence, the WK filters can be written:

$$\mathbf{w}_\mu(L) = \frac{|1 + L|^{2n}}{|1 + L|^{2n} + \lambda|1 - L|^{2m}}, \quad \mathbf{w}_\psi(L) = \frac{\lambda|1 - L|^{2m}}{|1 + L|^{2n} + \lambda|1 - L|^{2m}} = 1 - \mathbf{w}_\mu(L). \tag{2}$$

The above trend filter can be equivalently derived by solving the following penalised least square (PLS) problem:

$$\min_{\mu_t} \text{PLS} = \sum_t [(1 + L)^n (y_t - \mu_t)]^2 + \lambda \sum_t (\Delta^m \mu_t)^2,$$

as can be shown by direct differentiation. Also, after a transformation and with a change of sign, the PLS above coincides with the kernel of the joint Gaussian density of the observations and the trend, when  $y_t$  is generated according to (1). The connection with the signal-noise ratio makes clear that the Lagrange multiplier,  $\lambda$ , measures the variability of the noise component relative to that of the trend, and regulates the smoothness of the long-term component.

Using Whittle's result (1983, page 58), the ACGF of the final estimation error,  $e_t = \mu_t - \tilde{\mu}_t = -(\psi_t - \tilde{\psi}_t)$ , is equal to

$$g_e(L) = \frac{g_\mu(L)g_\psi(L)}{g_y(L)} = \frac{\lambda|1 + L|^{2n}}{|1 + L|^{2n} + \lambda|1 - L|^{2m}} \sigma_\zeta^2$$

The estimators  $\tilde{\mu}_t, \tilde{\psi}_t$ , are also known as *smoothed* or *final* estimators. From the operational standpoint, given a time series  $y_t$ , available at times  $t = 1, 2, \dots, T$ , the MMSE estimates of the components using information up to and including time  $t + l$ , denoted  $\tilde{\mu}_{t|t+l}$  and  $\tilde{\psi}_{t|t+l}$ , along with their mean square errors, are computed by the Kalman filter and the associated smoothing algorithms for the model (1), see Harvey (1989). For  $l = 0$  the estimators are also known as *filtered* or *real time* estimators. The treatment of initial conditions in the presence of nonstationarity is dealt with in de Jong (1991), Ansley and Kohn (1985) and Koopman (1997), and de Jong (1989) presents various smoothing algorithms; the connection with the WK signal extraction theory is discussed in Burridge and Wallis (1988).

The class of filters depends on the order of integration of the trend ( $m$ , which regulates its flexibility), on the order of the unit root at the Nyquist frequency ( $n$ , which *cæteris paribus* regulates the smoothness of  $\Delta^m \mu_t$ ), and  $\lambda$ , which measures the relative variance of the noise component. The filter proposed by Hodrick and Prescott (1997), enjoying large popularity in economics, arises for the combination  $m = 2, n = 0, \lambda = 1600$  for quarterly data. Gómez (2001) consider two types of Butterworth filters for which  $n = 0$  or  $m = n$ . Rational square wave trend-cycle filters have been introduced by Pollock (2000) using 5 ideal conditions (phase-neutrality, complementarity, symmetry, high- and lowpass conditions); as Pollock shows, they constitute the optimal filters for the decomposition (1) with the noise replaced by the process  $\psi_t = \Delta^{n-m} \kappa_t$ ; our framework thus encompasses rational square wave filters with  $n = m$ , which is perhaps the most interesting case, as it postulates a stationary and invertible representation for  $\psi_t$ . Finally, the multiresolution Haar scaling and wavelet filters (see Percival and Walden (1999)) occur for  $m = n = 1, \lambda = 1$ , in which case the trend filter and the cycle filter are both finite impulse response filters:  $w_\mu(L) = 0.25L^{-1} + 0.5L + 0.25L^{-1}$ ,  $w_\psi(L) = -0.25L^{-1} + 0.5L - 0.25L^{-1}$ .

The trend filter can also be characterised as a lowpass filter whose cutoff frequency depends on the three parameters. Frequency domain arguments can be advocated for designing the parameters so as to select the fluctuations that are in a specified periodicity range. This interpretation is already attested in Ng and Young (1990).

In particular, let  $w_\mu(\omega)$  denote the Fourier transform of the trend filter (2),  $w_\mu(\omega) = w_\mu(e^{-i\omega})$ ,  $\omega \in [0, \pi]$ ; as the latter is real and positive, it is coincident with the gain of the filter. The gain measures the amplification of the frequency components of the original process to obtain the corresponding components of the filtered series. That of the trend is a monotonically decreasing with  $\lambda$ , it is unit at the zero frequency and it is zero at the Nyquist frequency if  $n$  is greater than zero. The trend filter will preserve to a great extent

those fluctuations at frequencies for which the gain is greater than 1/2 and reduce to a given extent those for which the gain is below 1/2. This simple argument justifies the definition of a lowpass filter with cutoff frequency  $\omega_c$  if the gain halves at that frequency; see Gómez (2001), section 1.

Solving the equation  $w_\mu(\omega_c) = 1/2$ , the parameter  $\lambda$  is expressed as a function of the cutoff frequency and the orders  $m$  and  $n$ :

$$\lambda = 2^{n-m} \left[ \frac{(1 + \cos \omega_c)^n}{(1 - \cos \omega_c)^m} \right]. \quad (3)$$

In the light of this relationship,  $f(m, n, \omega_c)$  will denote the trend filter corresponding to the orders  $m$  and  $n$  and the cutoff  $\omega_c$ .

Figure 1 displays the gains of various trend filters for  $m, n = 1, 2, 3$  and two cutoff frequency, the first corresponding to  $\omega_c = \pi/20$  (a period of 10 years of quarterly observations) and  $\pi/2$ . The upper panels illustrate that for low cutoff frequency  $\omega_c = \pi/20$ , the gain is invariant to the values of  $n$ , whereas this is not the case for higher frequencies. The lower panels consider the effects of increasing the parameter  $m$ , given the others. Sharper gains are obtained with more appreciable differences at  $\pi/2$ . Notice that  $f(1, 1, \pi/2)$  corresponds to the gain of the Haar scaling filter ( $\lambda = 1$ ) and that  $f(2, 0, \pi/20)$  is close to the HP filter for quarterly observations, as the smoothness parameter corresponding to this cutoff frequency is  $\lambda = 1649$ . As  $m$  and  $n$  increase the gain gets closer to the ideal lowpass filter, with unit gain for  $\omega \leq \omega_c$  and zero for  $\omega > \omega_c$ .

### 3 Model based interpretation: embedding the trend-cycle decomposition

Economic time series only rarely admit the representation (1); nevertheless, applications of the class of filters (2) is widespread, as the popularity of the HP filter testifies; the bandpass nature could provide a justification for their use (see Gómez (2001)). However, when the available series  $y_t$  cannot be modelled as (1) it is not immediately clear how trends and cycles should be defined and how inferences on them should be made. In particular, the Kalman filter and the associated smoothing algorithms for the model (1) no longer provide the MMSE estimators of the components nor their MSE.

In this section we propose an embedding strategy that defines artificial trend and cyclical components whose optimal signal extraction filters are provided by (2) when a doubly infinite sample is available, and that rely on the Kalman filter and smoother associated to an appropriately specified state space model for the computation of the MMSE of the components and their MSE in real time. As a result, the optimal filter varies with the properties of the series under investigation.

This approach was initiated by Gómez (2001) and Kaiser and Maravall (2001). In the present section we provide a novel derivation of the model based interpretation of the filters (2) based on the decomposition of the innovation process into ARMA components with noninvertible roots and common stationary AR polynomial.

Let  $y_t$  denote a univariate time with ARIMA( $p, d, q$ ) representation, that we write

$$\phi(L)(\Delta^d y_t - c) = \theta(L)\xi_t, \quad \xi_t \sim \text{NID}(0, \sigma^2),$$

where  $c$  is a constant,  $\phi(L) = 1 - \phi_1 L - \dots - \phi_p L^p$  is the AR polynomial with sta-

tionary roots,  $\Delta = 1 - L$  and  $\theta(L) = 1 + \theta_1 L + \dots + \theta_q L^q$  is invertible. The (pseudo) autocovariance generating function of  $y_t$  is

$$g_y(L) = \frac{|\theta(L)|^2}{|1 - L|^{2d} |\phi(L)|^2} \sigma^2,$$

where  $|\theta(L)| = \theta(L)\theta(L^{-1})$ , and  $|\phi(L)| = \phi(L)\phi(L^{-1})$ .

Let us now introduce the following decomposition of the white noise disturbance  $\xi_t$ :

$$\xi_t = \frac{(1 + L)^n \zeta_t + (1 - L)^m \kappa_t}{\varphi(L)}, \quad (4)$$

where  $\zeta_t$  and  $\kappa_t$  are two mutually and serially independent Gaussian disturbances,  $\zeta_t \sim \text{NID}(0, \sigma^2)$ ,  $\kappa_t \sim \text{NID}(0, \lambda\sigma^2)$ , and

$$|\varphi(L)|^2 = \varphi(L)\varphi(L^{-1}) = |1 + L|^{2n} + \lambda|1 - L|^{2m}. \quad (5)$$

We refer to (5) as the spectral factorisation of the lag polynomial on the right hand side; the existence of the polynomial  $\varphi(L) = \varphi_0 + \varphi_1 L + \dots + \varphi_{q^*} L^{q^*}$ , of degree  $q^* = \max(m, n)$ , is guaranteed by the fact that the Fourier transform of the rhs is never zero over the entire frequency range; see Sayed and Kailath (2001).

In the light of (4)-(5), the series can be decomposed into orthogonal trend and cyclical components:

$$y_t = \mu_t + \psi_t,$$

$$\begin{aligned} \phi(L)\varphi(L)(\Delta^d \mu_t - c) &= (1 + L)^n \theta(L) \zeta_t, & \zeta_t &\sim \text{NID}(0, \sigma^2) \\ \phi(L)\varphi(L)\psi_t &= \Delta^{m-d} \theta(L) \kappa_t, & \kappa_t &\sim \text{NID}(0, \lambda\sigma^2) \end{aligned} \quad (6)$$

such that the trend has the same order of integration as the series (regardless of  $m$ ) and the cycle is stationary provided that  $m \geq d$ . An interesting case arises for  $m = d + n$ , for which the trend and the cycle have the same number of unit roots in the MA representation, at the  $\pi$  and zero frequency, respectively.

The decomposition is an artifact, as it does not necessarily correspond to a characteristic of the phenomenon under investigation (if it does the components would be estimated with the minimum MSE among all alternative decompositions); nevertheless, nothing prevents that artificial components are introduced and measured with the intent of selecting some fluctuations of interest.

The ACGFs of the components are respectively:

$$g_\mu(L) = w_\mu(L)g_y(L), \quad g_\psi(L) = w_\psi(L)g_y(L), \quad (7)$$

Obviously,  $g_y(L) = g_\mu(L) + g_\psi(L)$ . Given the availability of a doubly infinite sample, the optimal signal extraction filters are obtained from the ratio of the ACGFs of the components to that of  $y_t$ . Thus,  $\tilde{\mu}_t = w_\mu(L)y_t$  and  $\tilde{\psi}_t = w_\psi(L)y_t$ , with impulse response function given by (2), are the WK estimators of the components.

This simple argument shows that the signal extraction filter for the central data points will continue to be represented by (2), regardless of the properties of  $y_t$ , but this is the only feature that is invariant to those properties. The MSE of the smoothed components, as a matter of fact, depends on the ACGF of  $y_t$  as will be shown in the next section. Furthermore, the estimators  $\tilde{\mu}_{t+l|t}$ ,  $\tilde{\psi}_{t+l|l}$ , and the corresponding MSEs will be provided by the Kalman filter and smoother (if  $l \leq 0$ ) associated to the model (6), whose state space representation is presented in the appendix.

## 4 An upper bound for the estimation error variance

We can apply general principles and in particular Whittle's formula for obtaining the ACGF of the components' estimation error,  $e_t = \psi_t - \tilde{\psi}_t = -(\mu_t - \tilde{\mu}_t)$ :

$$g_e(L) = \frac{g_\mu(L)g_\psi(L)}{g_y(L)} = w_\mu(L)w_\psi(L)g_y(L) = \frac{\lambda|1 - L|^{2m}|1 + L|^{2n}}{|\varphi(L)|^4}g_y(L). \quad (8)$$

Let us denote  $g_x(L)$  the ACGF of the stationary process  $x_t = \Delta^d y_t$  and consider the factorisation:

$$g_e(L) = \frac{\lambda|1 - L|^{2(m-d)}|1 + L|^{2n}}{|\varphi(L)|^4}g_x(L) \equiv v(L)g_x(L).$$

Applying the Cauchy-Schwartz inequality, the estimation mean square error has an upper bound that can be broken down as follows:

$$\text{MSE}(e_t) = \frac{1}{\pi} \int_0^\pi g_e(\omega) d\omega \leq \frac{1}{\pi} \left[ \int_0^\pi v(\omega)^2 d\omega \right]^{1/2} \left[ \int_0^\pi g_x(\omega)^2 d\omega \right]^{1/2}.$$

The last factor depends on the ACGF of the stationary representation of the process and it is invariant to the trend-cycle filter; the first factor, on the other hand, depends solely on the properties of the filter and the true order of integration  $d$ .

We now consider how different values of  $m, n$  and  $\omega_c$  affect the uncertainty of the estimated components components, distinguishing three cases, according as to whether the series is stationary ( $d = 0$ ) or integrated up to the second order,  $d = 1, 2$ . Figure (2) displays the logarithm of  $\int v(\omega)^2 d\omega$  versus the cutoff frequency used in the determination of the smoothing parameter according to formula (3).

In the stationary case the components defined using high and low cutoff frequencies

are estimated with lower uncertainty. Moreover, for a given  $\omega_c$ , the upper bound decreases as  $m$  and  $n$  increase: this important feature holds also in the nonstationary case; however, the sensitivity to these parameters decreases quite rapidly, as can be seen from the second and third panels as we move from  $m = 2$  to  $m > 2$ . For nonstationary series,  $d = 1, 2$ , the upper bound decreases monotonically with the cutoff frequency,  $\omega_c$ . This implies that components defined using a lower cutoff, i.e. estimating a longer run (smoother) trend, are estimated with greater uncertainty. As  $\omega_c \rightarrow 0$ ,  $\lambda \rightarrow \infty$ , as it is clear from (3) and the decomposition (4) yields a deterministic trend represented by a polynomial in  $t$ .

## 5 Uncertainty and revisions

The previous section discussed how the nature of the filter affects the upper bound of the components MSE. We turn now to two case studies that illustrate how the reliability of the trend-cycle estimates depends on the cutoff frequency and the other parameters that regulate the flexibility and the smoothness of the filter, and the extent of the revision process<sup>1</sup>.

### 5.1 The decomposition of U.S. GDP

Our first illustration deals with the popular HP filter ( $m = 2, n = 0, \lambda = 1600$ ) adapted to the logarithm of the U.S. quarterly real gross domestic product (GDP, sample period 1947.q1-2003.q3). We consider three ARIMA models, with parameter estimates presented below, along with the Akaike and Bayesian information criteria (AIC and BIC, respectively), and the Ljung-Box portmanteau autocorrelation test with 8 lags (p-value in

---

<sup>1</sup>The computations in the paper were performed using the programming language Ox by Doornik (2001), and the library of state space functions `SsfPack` by Koopman, Shephard and Doornik (1999). The ARIMA models were estimated using E-views

parenthesis): the first is a simple random walk with drift, the second is an ARIMA(1,1,0) selected on the grounds of parsimony, and the third is the model adapted by Morley, Nelson and Zivot (2002), which provides a smaller AIC, but a larger BIC. The Ljung-Box statistic clearly points out that the RW model is misspecified.

**Random walk** [AIC = -6.09, BIC = -6.07,  $Q(8) = 33.13(0.00)$ ]

$$\Delta y_t = 0.0092 + \xi_t, \quad \xi_t \sim \text{NID}(0, 0.0172^2)$$

(0.0010)

**ARIMA(1,1,0)** [AIC = -6.18, BIC = -6.14,  $Q(8) = 8.98(0.25)$ ]

$$(1 - 0.3260 L)\Delta y_t = 0.0092 + \xi_t, \quad \xi_t \sim \text{NID}(0, 0.0109^2)$$

(0.0833)                      (0.0014)

**ARIMA(2,1,2)** [AIC = -6.20, BIC = -6.10,  $Q(8) = 2.12(0.71)$ ]

$$(1 - 1.4432 L + 0.8527 L^2)\Delta y_t = 0.0092 + (1 - 1.2240 L + 0.6914 L^2)\xi_t$$

(0.0853)                      (0.0753)                      (0.0011)                      (0.1124)                      (0.0938)

$$\xi_t \sim \text{NID}(0, 0.0106^2)$$

We consider now the trend-cycle decomposition with cutoff frequency  $\omega_c = 0.16$  corresponding to a period of about 10 years (39.7 quarters) and  $\lambda = 1600$ ; each ARIMA model implies a different representation for the components; estimates of the latter, computed by the Kalman filter and smoother for the corresponding state space model, are displayed in figure 3, where the trend component refers to the ARIMA(2,1,2) model. The HP cyclical component is also displayed in the second and the third panel, which

presents  $\tilde{\psi}_{t|T}$  for the last years in the sample, in order to appreciate better the differences among the estimates. The HP cycle is the MMSLE of the cycle under the IMA(2,2) model  $\Delta^2 y_t = (1 - 1.7771L + 0.7994L^2)\xi_t$ , which would not be selected for the series under investigation, being manifestly misspecified.

As figure 3 shows the HP estimates at the end of the sample differ from those that would be obtained from the model based decompositions. The optimal filter varies with the times series model for  $y_t$ ; however, the estimates for the ARIMA(1,1,0) and ARIMA(2,1,2) are indistinguishable, and those for the RW model are quite close. Differences arise with respect to the estimation MSE, plotted in the last panel. That arising from the HP filter is a clear underestimation of the MSE that would arise from models that provide a better representation of the series. We notice also that the latter is quite sensitive to the model selected, being greater for the ARIMA(1,1,0) model.

Leaving the other parameters unchanged ( $m = 2$  and  $n = 0$ ), we next consider the model-based filter that arise for the cutoff frequency equal to 1.26, corresponding to a period of 5 quarters and  $\lambda = 0.52$ .

This filter has been adopted by Artis, Marcellino and Proietti (2004) in order to extract a lowpass component reducing the amplitude of those fluctuations with periodicity less than the minimum cycle duration (one year and a quarter), which is employed used to date the peaks and troughs of the business cycle; as a matter of fact, in dating the business cycle, we should abstract from those high frequency movements that cannot qualify as cyclical because they are too short lived.

The estimates of the components and the estimation error MSE are presented in figure 4. Given the properties of the series under investigation (the high frequency components of  $\Delta y_t$  have little amplitude), the estimates of the highpass component do not vary with the model selected and are virtually coincident with the HP filter with  $\lambda = 0.52$ . The

difference pertains the MSE, which in turn is very small and close to zero. This reflects the fact that for an integrated series, components with high cutoff frequency are estimated with greater reliability.

The example fosters the conclusions that long run trends are estimated less reliably than short run ones. We notice in closing that both cyclical components are affected by a change in volatility, as documented in Stock and Watson (2002).

## 5.2 The ARIMA(1,1,0) case

The magnitude of the revision process is assessed comparing the final estimation error MSE with the real time one.

Since the MSE of the filtered and smoothed estimates is identical for the two components (recalling  $\mu_t - \tilde{\mu}_{t|t} = \tilde{\psi}_{t|t} - \psi_t$ ), let us concentrate on the cycle and denote the variance of the real time and final estimates respectively by  $\text{Var}(\psi_t|Y_t)$  and  $\text{Var}(\psi_t|Y_\infty)$ , where  $Y_t$  is the semi-infinite sample  $\{\dots, y_{t-1}, y_t\}$  and  $Y_{t\infty}$  is the doubly-infinite sample  $\{\dots, y_{t-1}, y_t, y_{t+1}, \dots\}$ . The variance of the filtered estimates admits the following decomposition:

$$\text{Var}(\psi_t|Y_t) = \text{Var}(\psi_t|Y_\infty) + V_R,$$

where  $V_R = \text{E}[(\tilde{\psi}_t - \tilde{\psi}_{t|t})^2]$  is the revision error variance. Thus the ratio

$$R = \frac{\text{Var}(\psi_t|Y_t)}{\text{Var}(\psi_t|Y_\infty)} = 1 + \frac{V_R}{\text{Var}(\psi_t|Y_\infty)}, \quad (9)$$

measures the relative importance of the revision process;  $R$  moves away from unity, which is the reference value that would be achieved were the components fully estimated in real time, as the variance of the revisions increases relative to the real time estimation error variance.

The ratio (9) clearly depends on the ARIMA model for  $y_t$ ; in this paper we limit the analysis of its behaviour to the fairly realistic and representative case when the series follows the ARIMA(1,1,0) process  $(1 - \phi L)(\Delta y_t - c) = \xi_t$ . If  $\phi$  is positive, the dynamics of  $\Delta y_t$  are dominated by low frequency components and viceversa; we mention that similar results hold for the ARIMA(0,1,1) process. Figure 5 displays the values of  $R$  against the cutoff frequency for different combinations of the pair  $m, n$ . Both the numerator and the denominator are evaluated by the steady state Kalman filter and smoother for the state space representation given in the appendix.

The main evidence can be summarised as follows:

- For a given  $\phi, \omega_c$  and  $m = 1, 2$ , increasing  $n$  enhances the relative magnitude of the revision process.
- In the RW case ( $\phi = 0$ ) we have the interesting property that choosing  $n = m$  makes  $R$  invariant to the cutoff frequency.
- For given  $\phi, \omega_c$  and  $n$ , the magnitude of the revision process increases with  $m$ . Hence the choice of a more flexible trend results *cæteris paribus* in larger revisions.
- Long run trends ( $\omega_c$  is low) are subject to comparatively smaller revisions if  $\Delta y_t$  is dominated by low frequencies fluctuations ( $\phi > 0$ ).

## 6 The Model Based Interpretation of Bandpass Filters

A popular approach to the measurement of the business cycle entails selecting all the fluctuations with a specified range of periodicities, namely those ranging from one and a half to eight years. If  $s$  denotes the number of observations in a year, the fluctuations with

periodicity between  $1.5s$  observations (e.g. 6 quarters, or 18 months) and  $8s$  observations (e.g. 32 quarters or 96 months) are included.

Given the two cutoff frequencies,  $\omega_{1c} = 2\pi/(8s)$  and  $\omega_{2c} = 2\pi/(1.5s)$ , the ideal *bandpass* filter has unit gain inside the interval  $[\omega_{1c}, \omega_{2c}]$  and zero outside.

This approach has been popularized by Baxter and King (1999), who propose a  $3s$ -terms approximation to the ideal filter; Christiano and Fitzgerald (2003) investigated the problem of finding the optimal linear approximation of the ideal filter, given a particular parametric model. They end up suggesting that for macroeconomic time series the filter derived assuming a random walk model for  $y_t$  is suitable.

In this section we consider bandpass filters constructed from the principle of decomposing the lowpass component in (6). Let us consider fixed values of  $m$  and  $n$  and two cutoff frequencies,  $\omega_{1c}$  and  $\omega_{2c} > \omega_{1c}$ , with corresponding values of the smoothness parameter  $\lambda_1$  and  $\lambda_2$ , determined according to (3). Obviously  $\lambda_1 > \lambda_2$ .

The trend-cycle decomposition corresponding to the triple  $m, n, \lambda_2$  (or, equivalently,  $m, n, \omega_{2c}$ ), is as in (6):

$$\begin{aligned} y_t &= \mu_{2t} + \psi_{2t}, \\ \Delta^d \mu_{2t} &= c + \frac{(1+L)^n}{\varphi_2(L)} \frac{\theta(L)}{\phi(L)} \zeta_{2t}, \quad \zeta_{2t} \sim \text{NID}(0, \sigma^2) \\ \psi_{2t} &= \frac{(1-L)^m}{\varphi_2(L)} \frac{\theta(L)}{\Delta^d \phi(L)} \kappa_{2t}, \quad \kappa_{2t} \sim \text{NID}(0, \lambda_2 \sigma^2) \end{aligned} \quad (10)$$

with  $|\varphi_2(L)|^2 = |1+L|^{2n} + \lambda_2 |1-L|^{2m}$ .

We can similarly define the trend-cycle decomposition corresponding to the triple  $m, n, \lambda_1$  (or, equivalently,  $m, n, \omega_{1c}$ ),  $y_t = \mu_{1t} + \psi_{1t}$ . As  $\lambda_1 > \lambda_2$  this decomposition features a lower cutoff frequency,  $\omega_1$ , thereby yielding a smoother trend. The components  $\mu_{1t}$  and  $\psi_{1t}$  are defined as in (10), with  $\varphi_1(L)$ ,  $\zeta_{1t} \sim \text{NID}(0, \sigma^2)$  and  $\kappa_{1t} \sim \text{NID}(0, \lambda_1 \sigma^2)$  replacing respectively  $\varphi_2(L)$ ,  $\zeta_{2t}$  and  $\kappa_{2t}$ . The polynomial  $\varphi_1(L)$  is such that  $|\varphi_1(L)|^2 =$

$$|1 + L|^{2n} + \lambda_1 |1 - L|^{2m}.$$

The lowpass component  $\mu_{2t}$  can in turn be decomposed using the orthogonal decomposition of the disturbance  $\zeta_{2t}$ :

$$\zeta_{2t} = \frac{\varphi_2(L)}{\varphi_1(L)} \zeta_{1t} + \frac{(1-L)^m}{\varphi_1(L)} \kappa_{1t} \quad (11)$$

with

$$\zeta_{1t} \sim \text{NID}(0, \sigma^2), \quad \kappa_{1t} \sim \text{NID}\left(0, (\lambda_1 - \lambda_2)\sigma^2\right), \quad \text{E}(\zeta_{1j}\kappa_{1t}) = 0, \forall j, t.$$

Under this setting, the ACGF of both sides of (11) is constant and equal to  $\sigma^2$ .

Replacing (11) into (10) and writing  $\mu_{2t} = \mu_{1t} + \psi_{1t}^*$ , enables  $y_t$  to be decomposed in three components, representing the lowpass, bandpass and highpass components, respectively.

$$\begin{aligned} y_t &= \mu_{1t} + \psi_{1t}^* + \psi_{2t}, \\ \Delta^d \mu_{1t} &= c + \frac{(1+L)^n}{\varphi_1(L)} \frac{\theta(L)}{\phi(L)} \zeta_{1t}, \quad \zeta_{1t} \sim \text{NID}(0, \sigma^2) \\ \psi_{1t}^* &= \frac{(1+L)^n (1-L)^m}{\varphi_1(L)\varphi_2(L)} \frac{\theta(L)}{\Delta^d \phi(L)} \kappa_{1t}, \quad \kappa_{1t} \sim \text{NID}(0, (\lambda_1 - \lambda_2)\sigma^2) \end{aligned} \quad (12)$$

and  $\psi_{2t}$  is the highpass component of the decomposition (10).

The decomposition can be cast in state space form and the components estimated using the Kalman filter; the latter automatically projects the bandpass filter onto the available sample, without the need to resort to forecast extensions or analytic derivation of the weights, and also provides the reliability measures, conditional on the ARIMA model for the series and its parameters.

As far as US GDP is concerned, figure (6) displays the smoothed estimates of the bandpass component,  $\text{E}(\psi_{1t}^* | Y_T)$ , conditional on the estimated ARIMA(1,1,0) model, and compares it with and the Baxter and King the highpass cycle, which is  $\text{E}(\psi_{1t} | Y_T)$ . Es-

sentially, the bandpass cycle is a smoothed version of the latter, devoid of high frequency fluctuations. The last panel shows that the bandpass is characterised by a higher estimation error variance in the central portion of the sample with respect to the highpass, but the situation is reversed at the extremes of the sample. We shall return to this issue shortly.

Given the availability of a doubly infinite sample, the Wiener-Kolmogorov estimator of the bandpass component is

$$\tilde{\psi}_{1t}^* = \mathbf{w}_{\psi_1^*}(L)y_t, \quad \mathbf{w}_{\psi_1^*}(L) = \frac{|1 + L|^{2n}|1 - L|^{2m}}{|\varphi_1(L)|^2|\varphi_2(L)|^2}(\lambda_1 - \lambda_2).$$

The gain of the filter for two combinations is plotted in the first panel of figure 6, which reports also that of the BK filter for comparison.

There are two interesting things to notice: first, denoting by  $\mathbf{w}_{\mu_i}(L)$  and  $\mathbf{w}_{\psi_i}(L)$ ,  $i = 1, 2$ , the WK filters for extraction of  $\mu_{it}$  and  $\psi_{it}$ , respectively, (11) implies  $\mathbf{w}_{\psi_1^*}(L) = \mathbf{w}_{\mu_2}(L) - \mathbf{w}_{\mu_1}(L) = \mathbf{w}_{\psi_1}(L) - \mathbf{w}_{\psi_2}(L)$ , and thus the bandpass filter is obtained as the contrast between two lowpass or highpass filters defined at different cutoffs.

The second implication of (11) is that  $\mathbf{w}_{\psi_1^*}(L) = \mathbf{w}_{\psi_1}(L)\mathbf{w}_{\mu_2}(L)(\lambda_2 - \lambda_1)/\lambda_1$ , which enables the interpretation of the historical bandpass filter as a cascade filter, such that the highpass filter defined at the cutoff  $\omega_{2c}$  is applied to the estimate of the lowpass (trend) component defined at the cutoff  $\omega_{1c}$ , rescaled by the factor  $(\lambda_2 - \lambda_1)/\lambda_1$ .

We now turn our attention to the comparison of the final estimation error variances concerning the bandpass and highpass components,  $\psi_{1t}^*$  and  $\psi_{1t}$ . Using the standard Wiener-Kolmogorov expressions for these variances, it is immediate to determine the following bounds for the efficiency of the bandpass estimates:

$$\min q(\omega) \leq \frac{\text{Var}(\psi_{1t}^*|Y_\infty)}{\text{Var}(\psi_{1t}|Y_\infty)} = \frac{\int_0^\pi g_{e1}(\omega)q(\omega)d\omega}{\int_0^\pi g_{e1}(\omega)d\omega} \leq \max q(\omega)$$

where  $g_{e1}(\omega)$  is the spectral generating function of the final estimation error  $\psi_{1t} - \tilde{\psi}_{1t}$ , see section 4, and  $q(\omega)$  is the Fourier transform of

$$q(L) = \frac{\lambda_1 - \lambda_2}{\lambda_1} \left( \frac{|\varphi_1(L)\varphi_2(L)|^2 - (\lambda_1 - \lambda_2)|1 + L|^{2n}|1 - L|^{2m}}{|\varphi_2(L)|^4} \right).$$

For the leading case of interest, that is  $\omega_{1c} = 2\pi/(8s)$  and  $\omega_{2c} = 2\pi/(1.5s)$ , the minima and maxima arising for some values of  $m$  and  $n$  are reported in the table below:

	$m = 1$		$m = 2$	
	$\min q(\omega)$	$\max q(\omega)$	$\min q(\omega)$	$\max q(\omega)$
$n = 0$	0.962	16.36	0.998	599.04
$n = m$	0.971	30.66	0.999	1171.58

These bounds entail that the variance ratio is likely to be greater than one, so it can be concluded that the final estimation error uncertainty is greater for the bandpass estimates.

As far as the trade-off between the estimation error reliability and revisions is concerned, there is no sharp theoretical result available, since it is specific to the ARIMA model for the series. Therefore, we illustrate the main findings with respect to US GDP. Table 1 reports the real time estimation error variance and revision error variance for high-pass and bandpass cyclical components extracted from US GDP, using 3 ARIMA models and the usual cutoffs  $\omega_{1c} = \pi/16$  and  $\omega_{2c} = \pi/3$

The trade-off is essentially the same for the bandpass component as that for the high-pass one: the estimation error variance of the real time (and the historical - given in the table by the difference between the real time and revision error variance) estimates decreases with  $m, n$ , but the variance of the revision increases. Thus the usual trade-off has to be faced. The choice of  $m, n$  which for given cutoffs minimises the variance of the revisions also maximises the size of the estimation error.

It might be thought that for the design of the bandpass filter, involving the choice of the parameters  $m$  and  $n$  given the cutoffs, one should adopt the criterion of minimising the real time error variance  $\text{Var}(\psi_{1t}^*|Y_t)$ , the latter representing a compromise of two elements of reliability, namely the sum of  $\text{Var}(\psi_{1t}^*|Y_\infty)$  and  $V_R$ ; this is illusory, however, as the variance of the theoretical component  $\psi_{1t}^*$  also varies with  $m$  and  $n$ .

It is clear from the table that both  $\text{Var}(\psi_{1t}^*|Y_t)$  and  $\text{Var}(\psi_{1t}|Y_t)$  decreases monotonically with both  $m$  and  $n$ ; the computations can be extended for higher values of the two parameters, confirming that these quantities decrease at an ever smaller rate, until the computations break down due to numerical instability.

The table also highlights a reduction in both the real time and revision error variance as we move from the highpass to the bandpass; however, the latter is more substantial so that the final estimation error variance increases (this is reflected also in the last panel of figure 6).

As a consequence, it cannot be concluded that the bandpass is preferable to the high-pass component.

## 7 Conclusions

The paper has focused on a class of trend-cycle filters that is optimal for a particular local trend model and that depends on the order of integration of the trend (trend flexibility), on the order of the unit root at the Nyquist frequency (trend smoothness), and the relative variance of the cyclical component. The trend filter can be characterised as a lowpass filter whose cutoff frequency depends on the three parameters.

By embedding the trend-cycle decomposition within the ARIMA time series model for a univariate time series we provide a model-based framework that enables inferences on

the unobserved components to be conducted by means of the Kalman filter and smoother associated to the relevant state space model. The components select certain features of the series and in this respect they represent an artificial construct. Nevertheless, the model-based interpretation allows to formalise the discussion on the relevant issue of the uncertainty by which certain signals or components are estimated.

In particular, it has been shown that for the type of nonstationary time series usually encountered in macroeconomics more stable components and long run trends and cycles, characterised by lower cutoff frequencies are estimated with less reliability. Moreover, in designing the filter the analyst faces some trade-offs. The purpose of this paper was that of illustrating them. In particular, if on the hand increasing the flexibility of the trend and its smoothness via the introduction on noninvertible MA features for a given cutoff frequency enhances the reliability of the signal, in real time the signal will be subject to larger revisions.

Smoothness priors have their costs, as the quest for smooth signals results in larger revisions and greater discrepancies between real time and final estimates. This ties in well with the intuition that, the smoother the trend, the more observations are needed before the estimate settles down to its final value, and thus the greater the amount of revision involved.

Finally, the bandpass component provides a cleaner signal with respect to the highpass cycle; nevertheless, it is not necessarily superior in terms of its reliability, since it is characterised by an higher final estimation error variance.

## A State space representation

The spectral factorisation  $\varphi(L)\varphi(L^{-1}) = a_0 + a_1(L + L^{-1}) + \dots + a_k(L^k + L^{-k})$ ,  $k = \max(m, n)$  with

$$a_j = I(j \leq n) \binom{2n}{n+j} + I(j \leq m) \binom{2m}{m+j},$$

where  $I(\cdot)$  is the indicator function, taking value 1 if the argument is true and 0 otherwise, can be achieved via the Riccati equation method presented in Sayed and Kailath (2001).

Let now  $\phi(L)^*$  denote the AR polynomial  $\phi(L)^* = \phi(L)\varphi_0^{-1}\varphi(L) = 1 - \phi_1^*L - \dots - \phi_{p+q^*}L^{p+q^*}$ , common to the representation of the trend and the cycle in (6), and let  $\theta_\mu(L) = (1 + L)^n\theta(L)$ , the MA polynomial of the trend component. Further, define the orders  $q_\mu = \max(p + q^*, n + q + 1)$ ,  $q_\psi = \max(p + q^*, q + 1)$ .

The state space representation of (6) consists of the measurement equation  $y_t = \mathbf{z}'\boldsymbol{\alpha}_t$ , with

$$\mathbf{z}' = [\mathbf{z}'_\mu, \mathbf{z}'_\psi], \quad \boldsymbol{\alpha}_t = [\boldsymbol{\alpha}'_{\mu,t}, \boldsymbol{\alpha}'_{\psi,t}]', \quad \mathbf{z}'_\mu = [\mathbf{i}'_{d+1}, \mathbf{0}'_{q_\mu}], \quad \mathbf{z}'_\psi = [1, \mathbf{0}'_{q_\psi}];$$

and the transition equation  $\boldsymbol{\alpha}_{t+1} = \mathbf{T}\boldsymbol{\alpha}_t + \mathbf{c} + \mathbf{R}\boldsymbol{\epsilon}_t$  with  $\boldsymbol{\epsilon}_t = \varphi_0^{-1/2}[\eta_t, \kappa_t]'$ ,

$$\mathbf{T} = \text{diag}(\mathbf{T}_\mu, \mathbf{T}_\psi), \quad \mathbf{c} = [c\mathbf{z}'_\mu, \mathbf{0}']', \quad \mathbf{R} = \text{diag}(\boldsymbol{\theta}_\mu, \boldsymbol{\theta}_\psi),$$

$$\mathbf{T}_\mu = \begin{bmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{0} & \mathbf{T}_\mu^* \end{bmatrix},$$

where  $\mathbf{A}$  is a  $d \times d$  upper triangular matrix with elements  $a_{ij} = 1, j \geq i$ , and  $a_{ij} = 0$ ,  $\mathbf{B}$  is  $d \times q_\mu$  matrix with zero elements except for the first column, which contains unit

elements,  $\mathbf{B} = [\mathbf{i}_d, \mathbf{0}]$ , and

$$\mathbf{T}_\mu^* = \begin{bmatrix} \boldsymbol{\phi}_\mu^* & \mathbf{I}_{q_\mu-1} \\ & \mathbf{0}' \end{bmatrix}, \mathbf{T}_\psi = \begin{bmatrix} \boldsymbol{\phi}_\psi^* & \mathbf{I}_{q_\psi-1} \\ & \mathbf{0}' \end{bmatrix},$$

$\boldsymbol{\theta}_\mu = [1, \theta_{\mu,1}, \theta_{\mu,2}, \dots, \theta_{\mu,q_\mu}]'$ ,  $\boldsymbol{\theta}_\psi = [1, \theta_{\psi,1}, \theta_{\psi,2}, \dots, \theta_{\psi,q_\psi}]'$ ,  $\boldsymbol{\phi}_\mu^* = [\phi_{\mu,1}^*, \phi_{\mu,2}^*, \dots, \phi_{\mu,q_\mu}^*]'$ ,  $\boldsymbol{\phi}_\psi^* = [\phi_{\psi,1}^*, \phi_{\psi,2}^*, \dots, \phi_{\psi,q_\psi}^*]'$ . The nonzero AR coefficients in  $\boldsymbol{\phi}_\mu^*$  and  $\boldsymbol{\phi}_\psi^*$  are the coefficients of  $\phi(L)^*$ , the nonzero MA coefficients in  $\boldsymbol{\theta}_\mu$  are those of the polynomial  $\theta_\mu(L)$ , and finally, those of  $\boldsymbol{\theta}_\psi$  are the coefficients of  $\theta(L)$ .
