SUMMARY

Structured matrix algebras and a generalized BFGS-type iterative scheme have been recently investigated to introduce low-complexity quasi-Newton methods, named LQN, for solving general (non-structured) minimization problems. In this paper we introduce the \( \mathscr{L}^k \)QN methods, which exploit \( \text{ad hoc} \) algebras at each step. Since the structure of the updated matrices can be modified at each iteration, the new methods can better fit the Hessian matrix, thereby improving the rate of convergence of the algorithm. KEY WORDS: unconstrained minimization; quasi-Newton methods; matrix algebras

1. INTRODUCTION

In this paper we study a new class of quasi-Newton (QN) algorithms for the minimization of a function \( f : \mathbb{R}^n \rightarrow \mathbb{R} \), which are a generalization of some previous methods introduced in Reference [1]. The innovative algorithms, named \( \mathscr{L}^k \)QN, exploit, in the quasi-Newton iterative scheme

\[
\textbf{x}_{k+1} = \textbf{x}_k - \lambda_k B_k^{-1} \nabla f(\textbf{x}_k),
\]

where the \( n \times n \) matrix \( A_k \) is picked up in a structured matrix algebra \( \mathscr{L}^k \), shares some significant property with \( B_k \) and is p.d. In (1), \( \varphi(\cdot, s_k, y_k) \) denotes a function updating p.d. matrices into p.d. matrices, whenever \( s_k^T y_k > 0 \), i.e.

\[
\begin{cases}
A \text{ p.d.} \\
s_k^T y_k > 0
\end{cases} \Rightarrow \varphi(A, s_k, y_k) \text{ p.d.}
\]
Condition (2) is in particular satisfied by the BFGS updating formula (5) in the next section, whereas a suitable choice of the step length $\lambda_k$ assures the inequality $s_k^T y_k > 0$ by using classical Armijo–Goldstein conditions (see (7) or Reference [2]). We underline that other possible updating formulas could be utilized (see e.g. Reference [3]).

Hessian approximations of type (1) were studied in the case $L^k = L$ for any $k$, where $L$ is a fixed space, and the matrix $A_k$ is the best approximation in the Frobenius norm of $B_k$ in $L$ [1]. Such matrix $A_k$, denoted by $L_{B_k}$, inherits positive definiteness from $B_k$. So, by property (2), $B_{k+1} = \varphi(L_{B_k}, s_k, y_k)$ is a p.d. matrix (provided that $s_k^T y_k > 0$). As a consequence, the LQN methods of Reference [1] yield a descent direction $d_{k+1}$.

If $L$ is defined as the set $sd U$ of all matrices simultaneously diagonalized by a fast discrete transform $U$ (see (8)), then the time and space complexity of LQN is $O(n \log n)$ and $O(n)$, respectively [1,4]. The latter result makes LQN methods suitable for minimizing functions $f$ where $n$ is large. In fact, numerical experiences show the competitiveness of LQN with limited-memory BFGS (L-BFGS), which is an efficient method for solving large-scale problems [4].

Moreover, a global linear convergence result for the class of NS LQN methods is obtained in References [1,5], by extending the analogous BFGS convergence result of Powell [6] with a proper use of some crucial properties of the matrix $L_{B_k}$.

The local convergence properties of LQN were studied in Reference [7]. It is proved, in particular, that LQN converges to a minimum point $x_*$ of $f$ with a superlinear rate of convergence whenever $\nabla^2 f(x_*) \in L$. The latter result is rather restrictive but suggests that, in order to improve LQN efficiency, one might modify the algebra of $L$ in each iteration $k$, i.e. introduce the $L^k$QN methods. This requires a concept of ‘closeness’ of a space $L^k$ with respect to a matrix $B_k$ and the construction, at each iteration, of a space $L^k$ as ‘close’ as possible to $B_k$. Two important properties of $B_k$ are that $B_k$ is p.d. and $B_k s_{k-1} = y_{k-1}$. So, we can say that a structured matrix algebra $L^k$ is ‘close’ to $B_k$ if $L^k$ includes matrices satisfying the latter properties, i.e. if

- the set $\{X \in L^k : X \text{ p.d. and } X s_{k-1} = y_{k-1}\}$ is not empty.

Once such space $L^k$ is introduced, we can conceive at least two $L^k$QN algorithms, based on the updating formula (1):

Algorithm 1: (1) with $A_k = L^k_{sy}$, where $L^k_{sy} \in L^k$ is p.d. and solves the previous secant equation $X s_{k-1} = y_{k-1}$.

Algorithm 2: (1) with $A_k = L^k_{B_k}$, where $L^k_{B_k}$ is the best least squares fit to $B_k$ in $L^k$.

The present paper is organized as follows. In Section 2 we recall some basic notions on quasi-Newton methods in unconstrained minimization and, in particular, the BFGS algorithm (Broyden et al., ’70) [2,8]. In Section 3 we describe the basic properties of the LQN methods, recently introduced in Reference [1]. The latter methods turn out to be more efficient than BFGS and extremely competitive with L-BFGS for solving large-scale minimization problems [4]. In order to improve the LQN efficiency, in Section 4 we introduce the innovative $L^k$QN algorithms. Assuming that $L^k$ is the set of all matrices diagonalized by a unitary matrix $U_k$, we translate the previous requirement • to a condition on $U_k$ (see (16)); then, we define in detail the $L^k$QN Algorithm 1. In Section 5 we prove that matrix algebras $L^k$ satisfying • exist without special conditions on the algorithm. Moreover, we illustrate how to compute such $L^k$, by expressing the corresponding matrix $U_k$ as a product of two Householder matrices. In Section 6 we introduce the $L^k$QN Algorithm 2, and we prove that the $\mathcal{N}$ version of such
algorithm is convergent. Moreover, we discuss some possible improvements of Algorithms 1 and 2 (see also Section 7). In particular, we define a method \( L^k \) QN which turns out to be superior to \( L \) QN in solving large-scale minimization problems.

2. QUASI-NEWTON METHODS FOR THE UNCONSTRAINED MINIMIZATION

We have to minimize a function \( f \), i.e. solve the problem:

\[
 f(x^*) = \min_{x \in \mathbb{R}^n} f(x) \quad \text{find } x^* \quad (3)
\]

Let us apply a QN method to the gradient vector function \( \nabla f \). Given \( x_0 \in \mathbb{R}^n \), \( B_0 = n \times n \) p.d., a QN method generates a sequence \( \{x_k\}_{k=0}^\infty \) convergent to a zero of \( \nabla f \), by exploiting a QN iterative scheme, i.e. a Newton scheme where the Hessian \( \nabla^2 f(x_k) \) is replaced by a suitable approximation \( B_k \):

\[
 x_{k+1} = x_k + \lambda_k d_k, \quad d_k = -B_k^{-1} \nabla f(x_k) \quad (\lambda_k \in \mathbb{R}^+) \quad (4)
\]

The matrix \( B_k \) is chosen p.d. so that the search direction \( d_k \) is always a descent direction \( (\nabla f(x_k)^T d_k < 0) \). How to choose the next Hessian approximation \( B_{k+1} \)? In secant methods \( B_{k+1} \) satisfies the secant equation, i.e. maps the vector \( s_k \) into the vector \( y_k \), where \( s_k = x_{k+1} - x_k \) and \( y_k = \nabla f(x_{k+1}) - \nabla f(x_k) \):

\[
 B_{k+1} s_k = y_k \quad \text{(Secant equation)}
\]

Note that for \( n = 1 \) the matrix \( B_{k+1} \) is a scalar and is uniquely defined as the difference quotient of the derivative function \( f'(x) \), i.e. we retrieve the ordinary secant method applied to \( f' \). In the general case \( (n > 1) \), the secant equation has many possible solutions and, as a consequence, several secant algorithms can be defined.

In BFGS (Broyden et al., '70) [2, 8, 9], the matrix \( B_{k+1} \) is defined as a rank-2 perturbation of the previous Hessian approximation \( B_k \):

\[
 B_{k+1} = \varphi(B_k, s_k, y_k) \quad \text{(BFGS)}
\]

where

\[
 \varphi(B, s, y) = B + \frac{1}{y^T s} s y^T - \frac{1}{s^T B s} B s s^T B
\]

By the structure of \( \varphi \), (1) BFGS is a secant method (2) BFGS has the following property: if \( B_k \) is p.d. then \( B_{k+1} \) is p.d. provided that the inner product between \( y_k \) and \( s_k \) is positive. Thus:

\[
 \begin{align*}
 B_k \text{ p.d.} \quad s_k^T y_k > 0 \quad \Rightarrow \quad & B_{k+1} = \varphi(B_k, s_k, y_k) \text{ p.d.} \\
 & \{ B_k \text{ p.d.} \}
\end{align*}
\]

The condition \( s_k^T y_k > 0 \) can be assured by a suitable choice of the step length \( \lambda_k \) [2]. In particular, it is satisfied if \( \lambda_k \) is chosen in the Armijo–Goldstein set

\[
AG_k = \{ \lambda \in \mathbb{R}^+ : f(x_k + \lambda d_k) \leq f(x_k) + c_1 \lambda d_k^T \nabla f(x_k) \quad \text{and} \quad d_k^T \nabla f(x_k + \lambda d_k) \geq c_2 d_k^T \nabla f(x_k) \},
\]

\[0 < c_1 < c_2 < 1 \quad (7)\]

The BFGS method has a local superlinear rate of convergence and an \( O(n^2) \) time and space complexity. As a consequence, in unconstrained minimization BFGS is often more efficient than the modified Newton algorithm. However, the implementation of BFGS becomes prohibitive when in problem (3) the number \( n \) of variables is large. Such large scale problems arise, for example, in the learning process of neural networks [4, 10].

3. \( \mathcal{L} \)QN METHODS

The aim of \( \mathcal{L} \)QN methods [1] is to reduce the complexity of BFGS by maintaining as more as possible a quasi-Newton behaviour. Several attempts were performed towards this direction (see e.g. References [11–13]). The main idea in Reference [1] is to replace \( B_k \) with a simpler matrix chosen in an algebra \( \mathcal{L} \). Let \( U \) be a \( n \times n \) unitary matrix and define \( \mathcal{L} \) as the set of all matrices diagonalized by \( U \) (\( \mathcal{L} = \text{sd} \ U \)):

\[
\mathcal{L} = \text{sd} \ U := \{ Ud(z) U^* : z \in \mathbb{C}^n \}, \quad d(z) = \begin{bmatrix} z_1 & \cdots & O \\ \vdots & \ddots & \vdots \\ O & \cdots & z_n \end{bmatrix} \quad (8)
\]

Pick up in \( \mathcal{L} \) the best approximation of \( B_k \) in the Frobenius norm. Call this matrix the best least squares fit to \( B_k \) in \( \mathcal{L} \) and denote it by \( \mathcal{L}_{B_k} \). Then apply the updating function \( \phi \) to \( \mathcal{L}_{B_k} \):

\[
B_{k+1} = \phi(\mathcal{L}_{B_k}, s_k, y_k) \quad (\mathcal{L}QN)
\]

If \( B_k \) is p.d. then \( \mathcal{L}_{B_k} \) is p.d. This fact is a simple consequence of the following expression of the eigenvalues of \( \mathcal{L}_{B_k} \):

\[
\mathcal{L}_{B_k} = Ud(z_k)U^*, \quad (z_k)_i = [U e_i]^* B_k [U e_i] \quad (9)
\]

Thanks to this property, we have also for \( \mathcal{L} \)QN methods that \( B_{k+1} \) inherits p.d. from \( B_k \) whenever \( s_k^T y_k > 0 \); moreover, under the same condition \( s_k^T y_k > 0 \), \( \mathcal{L}_{B_{k+1}} \) inherits p.d. from \( \mathcal{L}_{B_k} \):

\[
\begin{align*}
B_k \text{ p.d.} & \Rightarrow \mathcal{L}_{B_k} \text{ p.d.} \\
s_k^T y_k > 0 & \Rightarrow B_{k+1} \text{ p.d.} \Rightarrow \mathcal{L}_{B_{k+1}} \text{ p.d.}
\end{align*}
\]

(10)

Thus we have two possible descent directions.
1. The first one in terms of $B_{k+1}$, leading to a secant method:

$$d_{k+1} = -B_{k+1}^{-1} \nabla f(x_{k+1})$$

($B_{k+1}s_k = y_k$ since $\varphi(A, s_k, y_k)s_k = y_k \forall A$).

2. The second one in terms of $\mathcal{L}_{B_{k+1}}$, leading to a non-secant method:

$$d_{k+1} = -\mathcal{L}_{B_{k+1}}^{-1} \nabla f(x_{k+1})$$

($\mathcal{L}_{B_{k+1}}$ does not map $s_k$ into $y_k$, in general).

In References [1, 5] it is proved that $\mathcal{N}\mathcal{S}\mathcal{L}$ QN has a linear rate of convergence, whereas numerical experiences in Reference [4] show that $\mathcal{S}\mathcal{L}$ QN has a faster convergence rate.

Moreover, each step of any $\mathcal{L}$ QN method can be implemented so that the most expensive operations are two $U$ transforms and some vector inner products. This fact can be easily proved by examining the identity

$$z_{k+1} = z_k + \frac{1}{s_k^*y_k}|U^*y_k|^2 - \frac{1}{z_k^*|U^*s_k|^2}d(z_k)^2|U^*s_k|^2$$

(11)

and, in the secant case, the Shermann–Morrison–Woodbury inversion formula (see References [1, 4]). It is well known in the literature that this formula can be unstable from a numerical point of view [14]. However, the experiments performed on $\mathcal{F}\mathcal{L}$ QN methods have not pointed out significant difficulties (see Figure 1, Section 7 and Reference [4]). Thus, if $U$ defines a fast discrete transform ($\mathcal{L}$ structured), then $\mathcal{L}$ QN can be implemented with

SPACE COMPLEXITY: $O(n) =$ memory allocations for $U$, for vectors involved in iteration (11) and in computing $d_{k+1}$,

TIME COMPLEXITY (per step): $O(n \log n) =$ cost of $U \cdot z$.

Numerical experiences on large-scale problems [4] have shown that $\mathcal{F}\mathcal{L}$ QN, $\mathcal{L} = \mathcal{H}$ $\equiv$ Hartley algebra $= sdU$, $U_{ij} = 1/\sqrt{n} (\cos(2\pi ij/n) + \sin(2\pi ij/n))$ [15–17] has a good rate of convergence.
convergence and is competitive with the well-known L-BFGS method (for L-BFGS see References [8, 13, 18]). For example, in Figure 1 is reported the time required by LQN, and by L-BFGS, \( m = 13, 30, 90 \), to minimize the error function associated with a 34-38-2 neural network for learning the ionosphere data (see Reference [10]). Here the number of variables \( n \) is 1408 (for more details see Reference [4]). We recall that the L-BFGS procedure is defined in terms of the \( m \) pairs \( (s_j, y_j) \), \( j = k, \ldots, k - m + 1 \). Thus Figure 1 shows that strong storage requirements are needed \( (m = 90) \) in order to make L-BFGS competitive with LQN.

4. \( L^k \)QN METHODS

The idea in LQN methods is to replace \( B_k \) in \( B_k + 1 = \varphi(B_k, s_k, y_k) \) with a suitable matrix \( A_k \) of a structured algebra \( \mathcal{L} \). In Reference [1] this matrix \( A_k \) is the best approximation in the Frobenius norm of \( B_k = \varphi(A_{k-1}, s_{k-1}, y_{k-1}) \). In the present paper, we try to satisfy the secant equation

\[ Xs_{k-1} = y_{k-1} \tag{12} \]

by means of a suitable approximation \( A_k \) of \( B_k \) where \( A_k \) belongs to an algebra \( \mathcal{L} \). It is clear that in order to implement this new idea, the space \( \mathcal{L} \) and therefore the structure of \( \mathcal{L} \) must change at each iteration \( k \). The innovative \( L^k \)QN methods obtained in this way can better fit the Hessian structure, thereby improving the rate of convergence of the algorithm. As a matter of fact, some theoretical and experimental results reported in Reference [7] had already suggested that an adaptive choice of \( \mathcal{L} \) during the minimization process is perhaps the best way to obtain more efficient LQN algorithms.

Both the previous and the innovative procedures are shown in the following scheme:

BFGS:

\[
\begin{align*}
    x_{k+1} &= x_k - \lambda_k B_k^{-1} \nabla f(x_k) \\
    B_{k+1} &= \varphi(B_k, s_k, y_k)
\end{align*}
\]

\[ \downarrow \]

LQN:

Approximate \( B_k \) with a matrix of an algebra \( \mathcal{L} \)

Previous \( \leftarrow \leftrightarrow \rightarrow \) Present

with \( \mathcal{L}_{B_k} \) the best least squares fit to \( B_k \) in \( \mathcal{L} \)

with the matrix of \( \mathcal{L} \) solving the secant equation \( Xs_{k-1} = y_{k-1} \)

Let us introduce a basic criterion for choosing \( \mathcal{L}^k \), by assuming

\[ \mathcal{L}^k = \text{sd } U_k := \{ U_k d(z) U_k^* : z \in \mathbb{C}^n \}, \quad U_k n \times n \text{ unitary} \tag{13} \]

at the generic step \( k \).

Let \( A_k \) denote the matrix of \( \mathcal{L}^k \) that we have to update. So

\[ B_{k+1} = \varphi(A_k, s_k, y_k) \tag{14} \]
We require

(i) \(A_k\) is p.d.,
(ii) \(A_k\) solves the secant equation in the previous iteration, i.e. \(A_k\mathbf{s}_{k-1} = \mathbf{y}_{k-1}\).

Note that the latter conditions may yield a matrix \(A_k\) which is not the best approximation in Frobenius norm of \(B_k\) in \(\mathcal{L}^k\) (i.e. \(A_k \neq \mathcal{L}_k^k B_k\), in general).

Since \(A_k\) must be an element of the matrix algebra \(\mathcal{L}_k^k\), it will have the form

\[
A_k = U_k \mathbf{d}_k (U_k^* \mathbf{s}_{k-1})^T
\]

Then, the secant condition (ii) can be rewritten in order to determine \(\mathbf{d}_k\) via \(U_k^*\), i.e.

\[
(\mathbf{w}_k)_i = \frac{(U_k^* \mathbf{y}_{k-1})_i}{(U_k^* \mathbf{s}_{k-1})_i} \neq 0 \quad \forall i
\]

Finally, the positive definiteness condition (i) is verified if \((\mathbf{w}_k)_i > 0\). So, the basic criterion for choosing \(\mathcal{L}_k^k\) is the following one:

Choose \(U_k\) such that

\[
(\mathbf{w}_k)_i = \frac{(U_k^* \mathbf{y}_{k-1})_i}{(U_k^* \mathbf{s}_{k-1})_i} > 0 \quad \forall i
\]

and define \(\mathcal{L}_k^k\) as in (13).

Note that (16) is equivalent to say that \(\exists U_k\) unitary and \((\mathbf{w}_k)_i > 0\) such that the secant equation \(U_k d(w_k) U_k^* s_k = y_{k-1}\) is verified. By multiplying on the left by \(s_k^T\) the latter equation, we find that \(s_k^T y_{k-1} > 0\) is a necessary condition for the existence of \(U_k\) satisfying (16).

Once \(U_k\) is found, the corresponding space \(\mathcal{L}_k^k\) includes the desired matrix satisfying (i) and (ii). Denote this matrix by \(\mathcal{L}_k^k\) and define the new Hessian approximation \(B_{k+1}\) by applying \(\varphi\) to \(\mathcal{L}_k^k\).

\[
B_{k+1} = \varphi(\mathcal{L}_k^k, s_k, \mathbf{y}_k), \quad \mathcal{L}_k^k s_{k-1} = \mathbf{y}_{k-1} \quad (\mathcal{L}_k^k \text{QN})
\]

The two possible descent directions are

\[
d_{k+1} = \begin{cases} 
- B_{k+1}^{-1} \nabla f(x_{k+1}) & (I) \\
- (\mathcal{L}_k^k s_{k-1} = \mathbf{y}_{k-1}) & (II)
\end{cases}
\]

Note that both directions (I) and (II) are defined in terms of matrices satisfying the secant equation.

The following questions arise: There exists a unitary matrix \(U_k\) satisfying the condition (16)? Can this matrix be easily obtained?

5. PRACTICAL \(\mathcal{L}_k^k\) QN METHODS

We have observed that \(s_k^T y_{k-1} > 0\) is a necessary condition for the existence of a unitary matrix \(U_k\) satisfying (16). Actually, the following result holds.
Theorem 5.1
The existence of a matrix $U_k^*$ satisfying (16) is guaranteed if

$$y_{k-1}^T s_{k-1} > 0$$  \hspace{1cm} (17)

Observe that (17) is the condition required to obtain a p.d. matrix $B_k = \phi(A_{k-1}, s_{k-1}, y_{k-1})$, i.e. (17) is already satisfied (remember that the inequality $s_{k-1}^T y_{k-1} > 0$ can be obtained by choosing the step length $\hat{\lambda}_{k-1}$ in the $AG_{k-1}$ set).

Let $H(z)$ denote the Householder matrix corresponding to the vector $z$, i.e.

$$H(z) = I - \frac{2}{z^* z} zz^*$$  \hspace{1cm} (18)

$(H(0) = I)$. In order to prove Theorem 5.1, we need a preliminary result which turns out to be useful for the explicit computation of $U_k^*$.

Lemma 5.2
Given two vectors $s, y \in \mathbb{R}^n \setminus \{0\}$, let $r, x \in \mathbb{R}^n$ be such that $\|r\| \|x\| \neq 0$, $r_i \neq 0 \forall i$ and the cosine of the angle between $r$ and $x$ is equal to the cosine of the angle between $s$ and $y$, i.e.

$$\frac{r^T x}{\|r\| \|x\|} = \frac{s^T y}{\|s\| \|y\|}$$  \hspace{1cm} (19)

Set $u = s - y - ((\|s\| / \|r\|) r - (\|y\| / \|x\|) x)$, $p = H(u)s - (\|s\| / \|r\|) r = H(u)y - (\|y\| / \|x\|) x$ and

$$U^* = H(p) H(u)$$  \hspace{1cm} (20)

Then $U^* s = (\|s\| / \|r\|) r$, $U^* y = (\|y\| / \|x\|) x$ and

$$w_i = \frac{(U^* y)_i}{(U^* s)_i} = \frac{\|y\| r_i}{\|s\| x_i}$$

Proof
First observe that if $p = v - (\|v\| / \|z\|) z$, $v \in \mathbb{R}^n$, $z \in \mathbb{R}^n \setminus \{0\}$, then

$$H(p) v = \frac{\|v\|}{\|z\|} z$$

(in fact, $p^* v / \|p\|^2 = \frac{1}{2}$). As a consequence, for any unitary matrix $Q$ we have

$$p_1 = Q s - \frac{\|s\|}{\|r\|} r, \quad r \neq 0 \Rightarrow H(p_1) Q s = \frac{\|s\|}{\|r\|} r$$

$$p_2 = Q y - \frac{\|y\|}{\|x\|} x, \quad x \neq 0 \Rightarrow H(p_2) Q y = \frac{\|y\|}{\|x\|} x$$

Now choose $Q$ such that $p_1 = p_2$ or, equivalently,

$$Q(s - y) = \frac{\|s\|}{\|r\|} r - \frac{\|y\|}{\|x\|} x$$  \hspace{1cm} (21)
Such choice is possible provided that \( \|s - y\| = \|s\|/\|r\| \|r - (\|y\|/\|x\|)x\| \) from which we deduce the condition (19) on \( r \) and \( x \). A matrix \( Q \) satisfying (21) is \( H(u), u = s - y - ((\|s\|/\|r\|)r - (\|y\|/\|x\|)x) \). □

Now, in order to construct \( U_k^* \) satisfying (16), we need to prove the effective existence of \( r, s \in \mathbb{R}^n \) such that (19) holds with \( r_i x_i > 0 \).

**Proof of Theorem 5.1**

Given the two vectors \( s_{k-1} \) and \( y_{k-1} \), an example of vector pair \( (x, r) \) such that

\[
\frac{r^T x}{\|r\| \|x\|} = \frac{s_{k-1}^T y_{k-1}}{\|s_{k-1}\| \|y_{k-1}\|} \equiv \sqrt{\beta_{k-1}}, \quad r_i x_i > 0 \quad \forall i
\]

(22)

is the following:

\[
x = [1 \ vcdots \ v1]^T, \quad r = [v \ vcdots \ v1]^T, \quad \varepsilon = \varepsilon(\sqrt{\beta_{k-1}})
\]

where

\[
\varepsilon(x) = \frac{x}{1 + \sqrt{1 - x^2(n - 1) + x(n - 2)}}, \quad \varepsilon > 0 \quad \text{if} \quad 0 < x \leq 1.
\]

In fact, \( \varepsilon(x) > 0 \) if \( 0 < x \leq 1 \). So, under condition (17), we have that \( x \) and \( r \) have positive entries. Once \( x \) and \( r \) have been introduced, define the two vectors \( u \) and \( p \) as in Lemma 5.2, in terms of \( s_{k-1}, y_{k-1}, r, x \), and consider the corresponding Householder matrices \( H(u) \) and \( H(p) \). Then the matrix \( U_k^* \) is \( H(p)H(u) \). In fact, \( H(p)H(u) \) maps \( s_{k-1} \) and \( y_{k-1} \) into two vectors whose directions are the same of \( r \) and \( x \), respectively. So, by the condition \( r_i x_i > 0 \), the ratio of the two transformed vectors has positive entries:

\[
(w_k)_i = \frac{(U_k y_{k-1})_i}{(U_k^* s_{k-1})_i} = \frac{\|y_{k-1}\| \|r_i x_i\|}{\|s_{k-1}\| \|x_i r_i\|} > 0 \quad \forall i
\]

(23) □

Note that if we define \( U_k^* \) as the product of the two Householder matrices \( H(p) \) and \( H(u) \) (as above suggested), then the corresponding \( L^k \) QN method can be implemented with only \( O(n) \) arithmetic operations per step and \( O(n) \) memory allocations. This result is easily obtained from the identity (method (I))

\[
d_{k+1} = -\varphi(U_k d(w_k)U_k^* s_k y_k)^{-1} \nabla f(x_{k+1})
\]

by applying the Shermann–Morrison–Woodbury formula. Obviously, method (II) can be implemented with the same complexity.

**6. ALTERNATIVE \( L^k \) QN METHODS**

In this section an alternative \( L^k \) QN method is obtained in order to regain the best least squares fit condition.

Let \( U_k \) be a unitary matrix satisfying condition (16), so that the corresponding matrix algebra \( L^k \) includes a p.d. matrix \( L^k_{xy} \) solving the previous secant equation \( X s_{k-1} = y_{k-1} \).
Pick up in $\mathcal{L}^{k}$ the best approximation $\mathcal{L}_{B_k}^k$ in the Frobenius norm of $B_k$ and apply $\varphi$ to $\mathcal{L}_{B_k}^k$. So

$$B_{k+1} = \varphi(\mathcal{L}_{B_k}^k, \mathbf{s}_k, \mathbf{y}_k)$$  \quad \text{(Alternative $\mathcal{L}^k$QN)}

Since

$$B_k \text{ p.d.} \Rightarrow \mathcal{L}_{B_k}^k \text{ p.d.} \Rightarrow B_{k+1} \text{ p.d.} \Rightarrow \mathcal{L}_{B_{k+1}}^{k+1} \text{ p.d.}$$

the latter definition of $B_{k+1}$ leads to two possible descent directions which are expressed in terms of $B_{k+1}$ and in terms of $\mathcal{L}_{B_{k+1}}^{k+1}$, respectively. The former leads to a secant method, the latter to a non-secant one:

$$d_{k+1} = \begin{cases} -B_{k+1}^{-1} \nabla f(x_{k+1}) & \mathcal{L}^k \text{QN} \\ -(\mathcal{L}_{B_{k+1}}^{k+1})^{-1} \nabla f(x_{k+1}) & \mathcal{NS} \mathcal{L}^k \text{QN} \end{cases}$$

Since $\mathcal{NS} \mathcal{L}^k$QN is a BFGS-type algorithm where $\tilde{B}_k = \mathcal{L}_{B_k}^k$ (see Reference [1]) and, by (9), $\mathcal{L}_{B_k}^k$ satisfies the conditions $\det B_k \leq \det \mathcal{L}_{B_k}^k$ and $\text{tr} B_k \geq \text{tr} \mathcal{L}_{B_k}^k$, we can apply Theorem 3.2 of Reference [1], thereby stating the following convergence results.

**Theorem 6.1**
If the $\mathcal{NS} \mathcal{L}^k$QN iterates $\{x_k\}$, defined with $\lambda_k \in AG$, satisfy the condition

$$\frac{\|y_k\|^2}{y_k^T s_k} \leq M$$  \quad (24)

for some constant $M$, then a subsequence of the gradients converges to the null vector. If, moreover, the level set $\mathcal{I}_0 = \{x : f(x) \leq f(x_0)\}$ is bounded, then a subsequence of $\{x_k\}$ converges to a stationary point $x_*$ of $f$ and $f(x_k) \to f(x_*)$.

**Corollary 6.2**
Let $f$ be a twice continuously differentiable convex function in the level set $\mathcal{I}_0$. Assume $\mathcal{I}_0$ convex and bounded. Then all the assertions of Theorem 6.1 hold, moreover, $f(x_*) = \min_{x \in \mathbb{R}^n} f(x)$.

In the next section, experimental results will clearly show that the novel $\mathcal{NS} \mathcal{L}^k$QN outperforms the previous $\mathcal{NS} \mathcal{L}^k$QN [1] in which the space $\mathcal{L}$ is maintained unchanged in the optimization procedure. However, $\mathcal{NS}$ and $\mathcal{L}^k$QN methods cannot be applied in the present form to large-scale problems since no relation exists between $\mathcal{L}^{k+1}$ and $\mathcal{L}^k$ (or $U_{k+1}$ and $U_k$) which allows to compute the eigenvalues $z_{k+1}$ of $\mathcal{L}_{B_{k+1}}^{k+1}$ efficiently from the eigenvalues $z_k$ of $\mathcal{L}_{B_k}^k$. A simple strategy to avoid this inconvenience consists of the following three stages:

1. At the step $m_j$ introduce a space $\mathcal{L}^{m_j} = \text{sd} U_{m_j}$, where the unitary matrix $U_{m_j}$ satisfies the condition \bullet (written in terms of $m_j$ instead of $k$).
2. At the next steps \( k \geq m_j \), choose \( L^k = L^{m_j} \) until the matrix \( U_m \text{diag}([U^*_m y_{k-1}]/[U^*_m s_{k-1}]) \) remains p.d. or, equivalently, until the space \( L^{m_j} \) includes a p.d. matrix solving the secant equation \( Xs_{k-1} = y_{k-1} \).

3. Set \( m_{j+1} = k \), \( j := j + 1 \), and go to 1.

The numerical experiments on this modified alternative \( L^k \text{QN} \) algorithm confirm for the \( L^k \text{QN} \) method a satisfactory numerical behaviour of the Shermann–Morrison–Woodbury formula. Observe, in fact, that a possible instability of the latter formula could be in any case easily detected by a pathological increase of time and/or number of iterations, particularly if one requires high-precision stopping rules.

We may summarize the main ideas of the present paper in the following scheme:

\[
\text{BFGS:} \quad \begin{cases} 
  x_{k+1} = x_k - \lambda_k B_k^{-1} \nabla f(x_k) \\
  B_{k+1} = \varphi(B_k, s_k, y_k)
\end{cases}
\]

\( \downarrow \)

\( \text{\( L^k \text{QN} \): Approximate } B_k \text{ with a matrix of a structured algebra } L^{m_j}, \quad m_j \leq k, \)

\( \bullet \) (written in terms of \( m_j \) instead of \( k \))

Now \( L_{\text{sy}}(m_j = k) \)

Now \( L_{B_k}(m_j \leq k) \)

solving the secant equation \( Xs_{k-1} = y_{k-1} \) in \( L^k \) the best least squares fit to \( B_k \) in \( L^{m_j} \).

7. PERFORMANCE OF \( L^k \text{QN} \) METHODS

We have compared the performances of \( L^k \text{QN} \) and \( L \text{QN} \) methods in the minimization of some simple test functions \( f \) taken from Reference [2] (see Tables I and II) and in solving the more difficult problem cited in Section 3 where \( f \) has 1408 independent variables (see Table III and Figure 2). The \( L \text{QN} \) method is implemented with \( L = H \), where \( H \) is the Hartley algebra. The matrices \( U_k \) utilized in \( L^k \text{QN} \) methods are the product of two

Householder matrices, as suggested in Section 5 (see the proof of Theorem 5.1). Table III and Figure 2 refer to experiences performed on a Pentium 4, 2 GHz, whereas Tables I and II (as well as Figure 1) report results of experiments run on an Alpha Server 800 5/333.

Table I reports the number of iterations required by $\mathcal{N}\mathcal{L}$QN (Section 3) and $\mathcal{N}\mathcal{L}^k$QN (Section 6) to obtain $f(x_k) < \varepsilon$, $\varepsilon = 10^{-4}, 10^{-6}, 10^{-8}$. It is clear that the rate of convergence of non-secant methods may be considerably improved by changing the space $L$ at each iteration $k$. Recall that $\mathcal{N}\mathcal{L}$ methods are convergent.

The same set of benchmarks is exploited to study the behaviour of the algorithms $\mathcal{L}$QN (Section 3), $\mathcal{L}^k$QN (Section 6) and $\mathcal{L}^k$QN (I) (Section 4). Table II shows that the latter methods are faster than the $\mathcal{N}\mathcal{L}$ algorithms. Moreover, $\mathcal{L}^k$QN and $\mathcal{L}^k$QN (I) turn out to be superior to $\mathcal{L}$QN in most cases.

When $n$ is large, the best performances of $\mathcal{L}^k$QN is obtained by slightly modifying the alternative $\mathcal{L}^k$QN methods, following procedure 1–3 suggested at the end of the previous section. The unitary matrix $U_{m_j}$, defining the space $\mathcal{L}^{m_j} = \text{sd} U_{m_j}$ (see (13)), is in fact kept fixed until the quotients $w_i = [U_{m_j}^* y_{k-1}]/[U_{m_j}^* s_{k-1}]$, $k \geq m_j$, remain positive. The latter procedure allows to obtain a more significant information on the spectrum of the Hessian $\nabla^2 f(x_{k+1})$ at a lower cost with respect to $\mathcal{L}$QN.
As Table III and Figure 2 show, the performances of such modified alternative $\mathcal{N}^k\mathcal{N}$ and $\mathcal{N}^k\mathcal{N}$ algorithms are extremely encouraging for solving the ionosphere problem [10] where $n = 1408$. In particular, this can be seen by comparing the results with those illustrated in Figure 1.

ACKNOWLEDGEMENTS

A special thanks to Dario Fasino for his remarkable suggestions on the use of Householder matrices.
